It is shown that the experiments of A.M. Toader, J. P. Goff, M. Roger, N. Shannon, J. R. Stewart, and M. Enderle, Phys. Rev. Lett. **94**, 197202 (2005) do not provide definitive experimental evidence for ring exchange terms in the Hamiltonian of La_2CuO_4, even though such terms may be present.

In a recent paper, Toader *et al.* [1] claimed to provide definitive experimental evidence for ring exchange terms in the Hamiltonian of La_2CuO_4 by comparing the experimental antiferromagnetic static spin structure factor $S(\mathbf{Q})$ with high-temperature series expansion. Ring-exchange terms arise at intermediate coupling in the effective low-energy theory for the Hubbard model. The ring-exchange parameters deduced from Ref. [1] agree with those found earlier [2], and in terms of the Hubbard model they correspond to $\kappa \equiv t/U = 1/7.5$ with $t = 0.29\,\mathrm{eV}$.

Fig. 1 compares several results with the corresponding data in Fig.3 of Ref. [1]. The high-temperaure series expansion of $S(\mathbf{Q})$ in Ref. [1] are in units where $J/t = 2\widetilde{J}_2^{(1)}/t = 4\kappa - 64\kappa^3$ and they are represented by the two dashed lines, along with three of the experimental points in the upper right-hand corner. Our Quantum Monte Carlo (QMC) data for $U = 7.5t$ and $U = 10t$ are given respectively by circles and by squares linked by a dotted line as a guide to the eye. We used the determinental method with discretization step $\Delta\tau = 1/10$. When the QMC data appear to have reached a size independent value, we give as lower and upper error bars statistical fluctuations on, respectively, the smallest and largest result. The largest system size is typically $L \times L = 12 \times 12$. When the size dependence is still important, the upper error bar is an upper bound obtained by a $1/L$ extrapolation of the values for the two largest system sizes. Except for the lowest temperatures, the results have converged as a function of L. The horizontal scale for QMC is obtained from $J/t = 4t/U \equiv 4\kappa$ with temperature in units of t, so that the scale $J/(2T)$ depends only on the ratio κ. We also show as a dash-dot line the value of $S(\mathbf{Q})$ obtained from high-temperature series expansion of the Heisenberg model, [3] without ring exchange. We take $\hbar = 1$ for both the Heisenberg and QMC results so that the corresponding $S(\mathbf{Q})$ can be compared with QMC on an absolute scale. However, the absolute scale of the results of Ref. [1] is not given, but on a logarithmic scale this is just a shift of the origin that does not change the slope. So $S(\mathbf{Q})$ for the Heisenberg model and for QMC have all been shifted by precisely the same value to compare with Ref. [1]. Clearly, as expected, the larger the value of U in the QMC calculation, the better the agreement with the Heisenberg model. Note however that both values of U are much closer to the Heisenberg result than to the results of Ref. [1], despite the fact that $U = 7.5t$ should correspond to the exchange parameters (including ring) used in that reference.

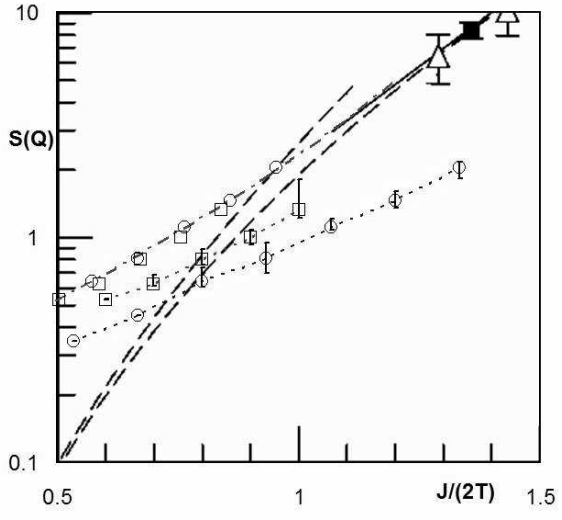

FIG. 1: High temperature series expansion from Ref. [1], lower dashed line is fifth order, higher dashed line is fourth order. Experimental results in upper right-hand corner. Heisenberg model [3] dashed-dotted line. QMC results $U = 7.5t$ circles and $U = 10t$ squares. When no error bars are indicated, there is additional scaling, as discussed in the text.

In Ref. [1] it was argued that agreement with experiment was better with ring exchange than without it because the high-temperature series results dove tail better with the experiment than the results obtained without ring exchange. We have here a counter example since with just a shift of the origin of the vertical axis of either the $U = 7.5t$ or $U = 10t$ results of the Hubbard model we can smoothly join the experimental data. As an added observation, we show in Fig. 1 that when our QMC data (represented by the same symbols as before but this time without error bars) are plotted as a func-

tion of $J/t = 2\widetilde{J}_2^{(1)}/t = 4\kappa - 64\kappa^3$, as suggested in Ref. [1], then they fall close to the Heisenberg curve and they all join smoothly the experiment.

The experimental results on $S(\mathbf{Q})$ are in the universal regime that can be described by the non-linear sigma model and hence they are insensitive to microscopic details, as noted in Ref. [1]. Our results suggest that unless this $S(\mathbf{Q})$ can be measured in the non-universal regime at higher temperature, it cannot lead to an accurate value of U/t (and hence of ring exchange contribution) by a smoothness argument, especially if additional parameters such as next-nearest-neighbor hopping are taken into account. Experiments involving measurement of $S(\mathbf{Q},\omega)$ at higher energies and shorter wavelengths are more informative, as discussed in Ref. [2], but even in that case it is important to also take into account detailed information on the band structure, including further neighbor hoppings, to obtain reliable values of U and consequent ring exchange terms.[4]

We are indebted to M. Gingras, J.-Y. Delannoy, M. Roger and N. Shannon for useful conversations.
